**Systematic Review**

**Impact of Non-Diet Approaches on Attitudes, Behaviors, and Health Outcomes: A Systematic Review**

Dawn Clifford, PhD, RD1; Amy Ozier, PhD, RD2; Joanna Bundros, BS1; Jeffrey Moore, BS1; Anna Kreiser, BS2; Michelle Neyman Morris, PhD, RD1

**ABSTRACT**

**Objective:** To determine the overall effect of non-diet, weight-neutral interventions on factors such as weight, biochemical measures, food and activity behavior, body image, and mental health.

**Design:** Systematic review of intervention literature.

**Setting:** Group classes in community and worksite settings (14 studies), and individual counseling (1) and online education (1) in college settings.

**Participants:** Eighteen research articles (representing 16 studies) evaluating non-diet interventions using quasi-experimental and randomized study designs with either a comparison or control group.

**Main Outcome Measures:** Anthropometric, physiological, psychological, and dietary intake.

**Analysis:** Systematic search of 168 articles and review of 18 articles meeting inclusionary criteria.

**Results:** Non-diet interventions resulted in statistically significant improvements in disordered eating patterns, self-esteem, and depression. None of the interventions resulted in significant weight gain or worsening of blood pressure, blood glucose, or cholesterol, and in 2 studies biochemical measures improved significantly compared with the control or diet group. Primary limitations were inconsistent definitions of non-diet approaches and the use of different assessment instruments for measuring outcomes.

**Conclusions and Implications:** Because of the long-term ineffectiveness of weight-focused interventions, the psychological improvements seen in weight-neutral, non-diet interventions warrant further investigation.

**Key Words:** non-diet, weight management, eating disorders, body image, mental health, overweight (J Nutr Educ Behav. 2015;47:143-155.) Accepted December 3, 2014.

**INTRODUCTION**

Dieting has become normative in Western culture, feeding a more than $60 billion industry per year,1 and includes a myriad of formal programs and plans. For many dieters, restriction by skipping meals, eliminating forbidden foods, or under-eating for the purpose of weight loss becomes a way of life. Regardless of the method used, weight loss attempts are often effective over the short-term, and yet over time weight is regained.2,4 Furthermore, emerging research is showing associations with dieting and weight gain5,7,9,10 and disordered eating patterns.7,12

Restricting food intake leads to a repetitive pattern of self-deprivation, which can result in disordered eating such as binging, weight changes including weight gain, and worsening self-image.13,14 Prospective studies indicate some risk factors for eating pathology including dietary restraint, perceived pressure for thinness, thin-ideal internalization, and body dissatisfaction.15

Despite mounting evidence of dieting failures, nutrition professionals continue to develop and implement nutrition education interventions aimed at assisting audiences with weight loss. Public health nutrition campaigns in schools, worksite wellness programs, and programs at the federal level frequently emphasize weight management as necessary for improving health.

One repercussion of society’s focus on weight loss is the stigmatization of and discrimination against overweight individuals16 in education,17-19 the workplace,20,21 and health care settings.22,23 Nutrition and health professionals as well as the lay public hold implicitly negative attitudes toward larger individuals24-27 without regard for the genetic, environmental, and sociocultural determinants of weight and health.28 Weight-based discrimination has been linked to poor body esteem,29 eating disorders,30 bullying,31 and depression.32

There is new evidence that weight-neutral, non-diet programming may be more effective at promoting permanent dietary and physical activity...
behavior change while minimizing weight stigma than traditional approaches.\textsuperscript{3,33,36} Non-diet–based interventions promote making healthful behavior changes, such as increased fruit and vegetable intake and increased physical activity, that result in improved fitness regardless of weight status.\textsuperscript{37}

The term Health at Every Size (HAES), trademarked by the Association for Size Diversity and Health in 2012, is often used synonymously with the term non-diet. The HAES paradigm is a weight-neutral approach centered on respecting body shape and size diversity, promoting a holistic approach toward wellness, ending weight discrimination and stigma, and promoting eating and exercise based on individualized hunger, satiety, nutritional needs, and pleasure.

Other concepts used in non-diet research include the Satter Eating Competence Model\textsuperscript{38} measured by the Eating Competence Satter Inventory\textsuperscript{19-41} and the Eating Competence Satter Inventory for Low Income,\textsuperscript{39} which assess an individual’s eating attitudes, food acceptance, internal regulation, and contextual skills around planning and preparing meals and snacks; Intuitive Eating\textsuperscript{42} measured by the Intuitive Eating Scale,\textsuperscript{43} and Intuitive Eating Scale-2,\textsuperscript{44} which assess the ability to tune into internal cues of hunger and fullness; and Mindful Eating\textsuperscript{45} measured by the Mindful Eating Questionnaire,\textsuperscript{46} which focuses on present moment awareness without judgment during the eating experience.

Competent eaters are more likely to be physically active,\textsuperscript{40} report eating more fruits and vegetables,\textsuperscript{40} have higher high-density lipoprotein (HDL) cholesterol and lower blood pressure,\textsuperscript{48} have a lower body mass index, and be more content with body weight.\textsuperscript{40} Intuitive eaters tend to enjoy a variety of foods, have better self-esteem and overall psychological well-being, and are less likely to internalize the thin ideal.\textsuperscript{44,49-51} In addition, intuitive eaters are less likely to engage in binge eating\textsuperscript{44,52,53} eat when they are anxious or stressed,\textsuperscript{54} or exhibit eating disorder symptomatology.\textsuperscript{50}

Many researchers have been implementing non-diet interventions and assessing their effects on anthropometrics, cholesterol, blood pressure, body image, depressions, stress, dietary restraint and disinhibition, dietary quality, and physical activity.\textsuperscript{23,33,34,36,53-67} The aim of this research was to conduct a systematic review to synthesize the peer-reviewed literature evaluating non-diet interventions to determine their effectiveness. Results are intended to guide the development of more effective intervention efforts and provide directions for future research.

**METHODS**

**Literature Search**

An initial search was conducted by a single author using the key terms Non-diet, Intuitive Eating, Health at Every Size, and Mindful Eating\textsuperscript{14,52,53} in the following databases over the course of a week from July 14 to July 20, 2013: Academic Search, Cumulative Index to Nursing and Allied Health Literature Plus, PubMed, and ScienceDirect. In addition, researchers searched for studies previously known to the authors and used backward searching from references of selected studies from July 15 to August 21, 2013. From these additional search methods, other studies were included that did not result from the search of key terms. No date cutoff criteria were established when searching, and the oldest study used was from 1998 (Figure).

**Inclusion and Exclusion Criteria**

Criteria for inclusion in the review were quasi-experimental or randomized study designs evaluating non-diet interventions with either a comparison or a control group. In addition, included studies were all published in English and involved human subjects. Studies were excluded if they were not published in full-text in peer-reviewed journals.

**Selection and Review Process**

The review process paralleled that of the PRISMA systematic review process.\textsuperscript{58} Full articles of the selected studies were retrieved and the authors divided up and individually reviewed all studies that met the inclusion criteria. A summary table was created in which each author documented study design, dose, duration and follow-up if applicable, sample size, non-diet concepts used, and anthropometric, physiological, psychological, and dietary intake outcome measures reported from the studies they reviewed (Table 1). Upon completion of this process, each author read and reviewed all studies to verify the key findings. Once the summary table was complete, 1 author verified all table data. Two authors reviewed full articles of the selected studies and reported individual findings of each outcome measure (Table 2). Both between- and within-group comparisons were reported comparing the non-diet group with either a diet group or a control group. If a study had 3 groups (non-diet group, diet group, and control group), comparisons between the non-diet group and the diet group were documented in Table 2. All significant and non-significant findings are reported in Tables 1 and 2. A third author reviewed the articles, and if there were discrepancies between the 2 completed tables, additional review was conducted to resolve the differences. All authors reviewed Table 2 for errors. Finally, to ensure accuracy, 3 authors reviewed the studies included in the analysis and summarized the overall findings, as evident in Tables 1 and 2. The summaries of findings from the 3 authors were compared and commonalities informed the overriding conclusions and implications for future research. Because of the diversity of study designs, outcome measures, non-diet approaches and intervention lengths, authors conducted a qualitative assessment of the current evidence.

**DISCUSSION**

A total of 168 abstracts were identified through the initial search. Once reviewed, 26 were categorized as intervention studies, 16 of which met the selection criteria and 10 of which were excluded because they were not quasi-experimental or randomized designs involving human subjects, did not include a control or comparison group, contained language consistent with a diet approach, or were not published in full text in peer-reviewed journals. The authors found 2 additional manuscripts that were not in the original search. The 18 research articles represented a total of 16 studies.\textsuperscript{2,3,33,34,36,55,57-67} Of the 16 studies, 14 were randomized
controlled trials (RCTs) and 2 were quasi-experimental. Articles that were excluded from the analysis were primarily due to a lack of control or comparison groups. Research by Marek et al. and Hendrickson et al. were excluded from Table 2 because the outcome measures reported differed substantially from the anthropometric, physiological, psychological, and dietary intake measures evaluated in the other studies, which made it challenging to compare. The study of Marek et al. was on participants with clinical eating disorders and the objective of Hendrickson et al. was to measure impulsiveness using the Barratt Impulsiveness Scale.

Overview of Studies

The majority of interventions (14 of 16) involved a series of group classes. One intervention included individual counseling and another was delivered through online learning modules. Interventions ranged from 50 minutes to 18 months; most interventions lasted 8–16 weeks.

Although weight loss is not the focal point of most non-diet interventions, 13 of the 16 interventions summarized here reported weight data. Of those, 5 resulted in no changes in weight among the non-diet groups, 6 led to non-significant weight loss, 1 led to significant weight loss, and 2 resulted in non-significant weight gain.

Of the 6 studies that reported blood lipid, blood glucose, and blood pressure data, 5 interventions led to improvements in some or all measures. One study reported no change in total blood pressure from pre- to postintervention. 2 reported reductions in systolic blood pressure, 3 led to reductions in diastolic blood pressure, and 1 led to no change in diastolic blood pressure. Two studies reported reductions in total, low-density lipoprotein, and/or HDL cholesterol. One reported that HDL cholesterol was reduced more in the control group than the non-diet group, and 1 reported a non-significant increase in total cholesterol postintervention. Only 2 studies reported biochemical measures that improved significantly compared with the diet group or control group.

Of the 6 studies that reported dietary restraint, 2 non-diet interventions led to significant reductions in dietary restraint compared with the other group from pre- to posttest. Two led to non-significant reductions in restraint, 1 led to no change in restraint, and 1 led to a non-significant increase in dietary restraint from pre- to posttest. Provencher et al. reported a significant decrease in disinhibition compared with the control group in their 2009 follow-up study, whereas Bacon et al. and Rapoport et al. reported a non-significant decrease in disinhibition after their interventions.

Seven studies reported outcomes related to body image avoidance, dissatisfaction, concern, or preoccupation. Of these, 1 reported a significant reduction in body image avoidance although the reduction was not maintained at 2-year follow-up, whereas 1 reported a non-significant reduction. Two studies reported a significant reduction in body image dissatisfaction. Two studies reported outcomes related to body image avoidance and concern, respectively, after their non-diet interventions.

Nine studies included in the review reported physical activity data. One study reported significant increases in energy expenditure from pre- to postintervention compared with controls. Carroll and colleagues were the only researchers to obtain post data from most participants to measure changes in fitness levels from pre to post. They reported significant improvements in maximal oxygen consumption (peak VO2) in the non-diet group compared with control. Although physical activity declined in both intervention and control groups in the WebHealth study, physical activity in the intervention group reduced significantly less than in the control group as college students adapted to their independent life stage. Keeler and colleagues found that reported physical activity stage of change increased significantly.

compared with controls. Two interventions resulted in non-significant increases in physical activity\textsuperscript{59,66} and 4 reported no change.\textsuperscript{58,62,65,67}

Greene and colleagues\textsuperscript{60} were the only researchers to report a significant improvement in diet quality (increased fruit and vegetable intake) after the intervention compared with controls.

All studies that tracked changes in disordered eating reported improvements in the non-diet groups from pre to post.\textsuperscript{2,3,57,59,66,67} Bacon et al\textsuperscript{2,3} and Ciliska\textsuperscript{57} reported significant reductions in self-reported bulimic behaviors in the non-diet groups compared with the diet and control groups, respectively. Disordered eating behaviors remained unchanged in most studies; however, binge eating scores were reduced in both non-diet groups and diet groups.\textsuperscript{59,66} Self-esteem improved from pre to post in all 4 studies\textsuperscript{3,36,57,66} that included this measure, with 2 studies finding significant improvements compared with the diet group\textsuperscript{2,3} or control.\textsuperscript{57}

Emotional health improved in all 5 interventions that tracked such outcomes.\textsuperscript{2,3,57,66,67,69} Reductions in depression were statistically significantly lower from pre to post compared with the other group in 3\textsuperscript{40,41,66,70} of the 467 studies that tracked components of emotional health. Furthermore, Carroll and colleagues\textsuperscript{69} found that emotional control and stability and general well-being improved significantly from pre to post compared with a control group.

Overall, differences in biochemical measures and weight outcomes between the diet and non-diet groups were inconsistent, with more consistent differences in psychological measures. For example, Tanco et al\textsuperscript{67} found a similar weight reduction between diet and non-diet groups, but the non-diet group had a statistically significant improvement in depression scores compared with the diet group. In general, most between-group differences are found in psychological assessments such as depression, self-esteem, disordered eating, and body image, especially when the non-diet intervention is compared with a diet intervention. These overall findings were similar to conclusions made by Schaefer and Magnuson,\textsuperscript{70} who reviewed 20 interventions that encouraged participants

to eat according to internal signals. They also noted the consistent psychological advantages of programs that emphasize a non-diet approach and the lower attrition rates of non-diet programs compared with diet programs. Because an individual’s health and well-being is affected by more than just diet and exercise, this primary finding warrants further investigation of non-diet approaches for health promotion.

Limitations

Considering that non-diet interventions are in their infancy of being implemented by researchers and practitioners, this systematic review presents inherent limitations. With limited non-diet interventions available to assess, all studies were included in the analysis that had a comparison or control group, regardless of the design quality or measure of statistical power.

Another limitation is the wide range of outcomes measured (Table 2). As an example, some studies used weight as an outcome variable whereas others did not. Some researchers used the non-diet approach of intuitive eating whereas others used mindful eating and yet others articulated their intervention with HAES or the Satter Eating Competence Model. Restraining and/or disinhibition were variables measured individually or together in some studies whereas other studies did not measure these behaviors. These variables also lack consistency in terms used to describe the non-diet approach. A contributing factor was that various assessment tools were used to measure similar study variables, which made it challenging to offer generalized statements about validity and reliability.

Some researchers chose to compare a non-diet intervention with a diet intervention whereas others compared the non-diet group with a control group who did not receive an intervention. These differences limit comparisons between studies and are noted in Table 2.

An inherent limitation includes the self-reported nature of the dietary intake and physical activity data. Duration of interventions also varied. In addition, studies that included follow-up of $\geq 1$ year were limited. Also, only 2-year follow-up was conducted; longer follow-up (eg, 5 years) is recommended before making conclusive statements about long-term benefits. Furthermore, a lack of consistency was evident in the populations studied, with samples ranging from a general student population to those with a diagnosed eating disorder. The samples also greatly varied in size. Control groups were different between studies and attrition rates varied, thus influencing final outcomes.

Confounding factors may have also influenced results of various studies. As an example, the study by Marek and colleagues reported a significant increase in negative affect from a clinical sample after the mindfulness intervention. At first glance, this implies that the mindfulness-based intervention had a negative effect. However, this was a clinical sample of individuals diagnosed with anorexia nervosa, bulimia nervosa, or eating disorders not otherwise specified, who most likely presented with psycho-comorbidities possibly influencing the cognitive process that occurs with mindfulness.

Another possible confounding factor was how the non-diet programs were actually implemented. The study by Carroll et al used the WHEEL intervention that was “designed to be in line with HAES,” yet the acronym stands for Weight, Healthy Eating, and Exercise in Leeds. Although HAES is considered a weight-neutral approach, this acronym implies that the intervention had a weight management focus. This suggests that there is significant variation in the attitudes of non-diet researchers toward the objective of weight-neutrality.

The 16 studies included in this systematic review included RCT and quasi-experimental designs to determine the impact of non-diet interventions on various anthropometric, physiological, psychological, and dietary intake outcomes. Despite the numerous limitations outlined that limit the generalizability of this summary, the literature suggests potential efficacy of non-diet interventions on several outcomes including improved blood lipids, glucose, and blood pressure; decreased dietary restraint and disinhibition, emotional eating, and eating disorder symptoms; increased body image, self-esteem, physical activity; and improved dietary patterns. In addition, these improvements are made without the negative effects often associated with weight-based interventions, including increased dietary restraint and subsequent disinhibition, weight cycling, increased body dissatisfaction, and high program attrition rates.

IMPLICATIONS FOR RESEARCH AND PRACTICE

A call to action is evident from this systematic review for more RCTs using non-diet approaches with standardized outcome variables and assessment tools. However, the studies included in this systematic review provide evidence that various non-diet interventions influence variables beyond weight. These include eating behavior, biochemical indices, fitness, anthropometrics, nutrient and energy intake, body image, depression, anxiety, and disordered eating.

In addition, the use of a standardized definition of non-diet is warranted. The HAES principles written by members of the Association for Size Diversity and Health can serve as a consistent definition that can guide future non-diet research. Skills training for these methods must stay true to the HAES message, which “acknowledges that good health can best be realized independent from considerations of size. It supports people—of all sizes—in addressing health directly by adopting healthy behaviors.”

This systematic review provides evidence in support of non-diet approaches, but more research is needed in this area. Obtaining research funding is needed to continue building the science base for non-diet approaches. Practitioners and researchers must think outside the box when searching for potential grant opportunities. These opportunities may present themselves under the auspices of obesity prevention and treatment. Because the term obesity prevention is directly at odds with a weight-neutral approach, researchers aiming to evaluate the effectiveness of non-diet approaches are encouraged to consider non-diet interventions that are likely to positively affect eating behavior and disordered eating.
interventions may struggle to obtain funding, further biasing the research.

Non-diet approaches that include HAES concepts provide a nontraditional paradigm of achieving behavior change through a focus on overall health. Traditional weight management paradigms have shown to be ineffective in the long term and psychologically damaging. This review highlights the psychological improvements often seen in non-diet interventions. Psychological distress may be a factor contributing to high metabolic risk, and non-diet interventions may at least minimize the increased psychological stress associated with behavior change.

Non-diet approaches to health promotion provide an alternative means of influencing psychological, emotional, and physiological change while also affecting eating behavior. The results of this systematic review suggest that future research developing and evaluating standardized methods, assessment tools, and non-diet terminology is needed to strengthen the evidence base for practitioners implementing interventions aimed at enhancing the health and overall well-being of individuals and groups served.
